#### Abstract

An uncertainty quantification scheme is constructed based on generalized Polynomial Chaos (PC) representations. Two such representations are considered, based on the orthogonal projection of uncertain data and solution variables using either a Haar or a Legendre basis. Governing equations for the unknown coefficients in the resulting representations are derived using a Galerkin procedure and then integrated in order to determine the behavior of the stochastic process. The schemes are applied to a model problem involving a simplified dynamical system and to the classical problem of Rayleigh-Bénard instability. For situations involving random parameter close to a critical point, the computational implementations show that the Wiener-Haar (WHa) representation provides more robust predictions that those based on a Wiener-Legendre (WLe) decomposition. However, when the solution depends smoothly on the random data, the WLe scheme exhibits superior convergence. Suggestions regarding future extensions are finally drawn based on these experiences.

 $\textit{Key words:}\ \text{Wavelets},\ \text{Polynomial Chaos},\ \text{stochastic process},\ \text{uncertainty quantification}$ 

#### 1 Introduction

The development of uncertainty quantification (UQ) schemes has been the subject of much recent interest, arising in large part due to the the increasing availability of large parallel computing platforms, the concurrent evolution of advanced numerical methods and algorithms, and the the development of complex physical and computational models. Uncertainty quantification can be instrumental in the development of these models, e.g. for the purpose of validation or in support of decision making analysis. This paper is part of an effort that explores the application of PC representations [1–8] to develop UQ methods for thermo-fluid problems.

Polynomial Chaos based methods have been extensively used for uncertainty quantification (UQ) in engineering problems of solid and fluid mechanics (e.g. analysis of stochastic elastic structures [8, 9], flow through porous media [10,11], incompressible and zero-Mach-number flows [12–14], thermal problems [15,16], as well as combustion and reacting flows [17–19]). One of the attractive features of PC representation concerns the efficiency of the resulting schemes, which can yield accurate predictions of the uncertainty at a small fraction of the cost of a Monte-Carlo approach [13].

One of the drawbacks of spectral PC representations, however, concerns potential limitations in situations where complex solutions arise, or when the dependence of the solution on the random input data varies rapidly. This limitation has been well-known based on experiences with Wiener-Hermite (WHe) representations. In particular, the analysis of Chorin [7] indicates that in complex problems involving shock formation or an energy cascade, the WHe representation may lose its advantages or cease to be practical.

In this paper we address a similar but different difficulty, arising in the case a

random parameter in the neighborhood of a critical point. We further restrict our attention to particular situations where the solutions remain smooth and well behaved, but which can change dramatically, or even discountinously, according to specific values of the uncertain data. Such sensitivity of the solution with regard to the random data can be viewed as a parameter shock or bifurcation. For reasons similar to those analyzed in [7], one may expect that Wiener-Hermite or other spectral expansions to fail to adequately describe the stiff (or discontinous) dependence of the solution on the random data. This study explores the possibility of overcoming this difficulty by using a wavelet-based PC expansion. In contrast to global basis functions, wavelet representations naturally lead to localized decompositions which suggest the possibility of a more robust behavior albeit at the expense of slower rate of convergence.

Being our first attempt in this direction, we restrict our attention to the one of the simplest families of wavelets, namely the Haar basis. In section 2, the Wiener-Haar expansion of solutions dependent on random data is introduced, and the salient features of the resulting PC representation are briefly outlined. In section 3, we first address a simple model problem consisting of a dynamical system having two isolated fixed points. Depending on specific realizations of the random initial conditions, the solution converges to one fixed point or the other. Numerical simulations indicate that, the WHa scheme can effectively resolve the random process, but that a WLe expansion is unsuitable in this case. A more complex problem is considered in 4, based on a stochastic version of the Rayleigh-Bénard. Specifically, we consider two cases involving a random Rayleigh number, with the uncertainty range either containing the critical point or lying entirely above the critical value. In both cases, the behavior of WHa and WLe expansions is contrasted. Major findings and possible extensions are finally outlined in section 5.

## 2 The Wiener-Haar expansion

In this section, we construct a WHa representation of a stochastic process. We start in section 2.1 with the decomposition of a one-dimensional probability space using Haar's wavelets, and construct in section 2.2 the associated orthonormal decomposition of a random process. The construction is then generalized to the multi-dimensional case in section 2.3. Solution methods are given in section 2.4, together with a brief discussion of similarities and differences with spectral PC constructions [12,13].

Let  $\theta$  be a random variable with given statistics. We denote by p(x) the probability that  $\theta < x$ , and assume that p(x) is a continuous strictly increasing function of x defined on a real interval (a, b), such that  $-\infty \le a < b \le \infty$ ,  $p(a) \equiv 0$  and  $p(b) \equiv 1$ . Although extension to the infinite case is possible, we shall exclusively deal with the situation where a and b are finite. Using p(x), the probability density function of x on (a, b) is given by:

$$pdf(x) \equiv \frac{dp(x)}{dx} > 0, \quad \forall x \in (a, b);$$
$$pdf(x) \equiv 0, \quad \forall x \notin (a, b).$$

Based on the assumed properties of p(x), it follows that for all  $y \in [0, 1]$  there is a unique  $x \in [a, b]$  such that p(x) = y. Consequently, we define the one to one mapping

$$y \in [0, 1] \longrightarrow x \equiv p^{-1}(y) \in [a, b].$$
 (1)

## 2.1.1 Haar scaling functions

The scaling function of the Haar system, denoted by  $\phi^{w}(y)$ , is given by

$$\phi^{\mathbf{w}}(y) = \mathbf{I}_{[0,1)}(y) = \begin{cases} 1 & 0 \le y < 1, \\ 0 & \text{otherwise.} \end{cases}$$
 (2)

Introducing the scaling factor j and the sliding factor k, we denote by

$$\phi_{i,k}^{W}(y) = 2^{j/2} \phi^{W}(2^{j}y - k), \tag{3}$$

the scaled Haar functions. Now, let  $\{V_j\}_{j=0}^{\infty}$  be the sequence of function spaces defined by  $V_j = \text{span}\{\phi_{j,k}^{\text{w}}, k \in [0, 2^j - 1]\}$ , and denote by  $P^j$  the projection of f onto the space  $V_j$ ; we thus have:

$$P^{j}f = \sum_{k=0}^{2^{j}-1} f_{j,k} \phi_{j,k}^{\mathbf{w}}(y), \tag{4}$$

where the coefficients are given by:

$$f_{j,k} = \int_{0}^{1} f(y)\phi_{j,k}^{W}(y)dy.$$
 (5)

#### 2.1.2 Haar wavelets

The detail function  $g^{j-1} \in V_j$  is defined as the difference between two successive resolution levels, namely:

$$g^{j-1} = P^j f - P^{j-1} f. (6)$$

To obtain an expression of the detail function, we introduce the Haar function:

$$\psi^{\mathbf{w}}(y) \equiv \frac{1}{\sqrt{2}} \phi_{1,0}^{\mathbf{w}}(y) - \frac{1}{\sqrt{2}} \phi_{1,1}^{\mathbf{w}}(y) = \begin{cases} 1, & 0 \le y < \frac{1}{2} \\ -1, & \frac{1}{2} \le y < 1 \\ 0, & \text{otherwise} \end{cases}$$
 (7)

The Haar function is the *mother wavelet* that generates the wavelet family:

$$\psi_{j,k}^{\mathbf{w}}(y) = 2^{j/2} \psi^{\mathbf{w}}(2^{j}y - k), \quad j = 0, 1, \dots, \text{ and } k = 0, \dots, 2^{j} - 1.$$
 (8)

From this definition we have

$$\int_{0}^{1} \psi_{j,k}^{w}(y) dy = 0, \quad \text{and} \quad \int_{0}^{1} \psi_{j,k}^{w} \psi_{l,m}^{w} dy = \delta_{jl} \delta_{km}. \tag{9}$$

Consequently, the set  $\{\psi_{j,k}^{\mathrm{w}}; j=0,1,\ldots,\infty; k=1,\ldots,2^{j}-1\}$  is an orthonormal system, and any function  $f\in L^{2}([0,1])$  can be arbitrarily well approximated by the sum of its mean and a finite linear combination of the  $\psi_{j,k}^{\mathrm{w}}(y)$ .

In terms of wavelets, the detail function can be expressed as:

$$g^{j-1}(y) = \sum_{k=0}^{2^{j-1}} d_{j,k} \psi_{j-1,k}^{\mathbf{w}}(y), \tag{10}$$

while  $P^{j}f$  is given by:

$$P^{j}f = P^{0}f + \sum_{l=0}^{j-1} \sum_{k=0}^{2^{l}-1} d_{l,k} \psi_{l,k}^{w}(y).$$
(11)

## 2.2 Wavelet approximation of a 1-D random process

We now seek a wavelet representation of a random process  $X(\theta)$ , where  $\theta$  is a random variable satisfying the assumptions of the previous section. Specifi-

cally, we consider an expansion of the form:

$$X(\xi(\theta)) = X_0 + \sum_{j=0}^{\infty} \sum_{k=0}^{2^{j-1}} X_{j,k}^{w} W_{j,k}(\xi(\theta)),$$
(12)

where  $X_{j,k}^{w}$  are the coefficients of the wavelet approximation of  $X(\xi)$ . Using the one to one mapping given by Eq. (1), the following relation holds:

$$W_{j,k}(\xi \in [a,b]) \equiv \psi_{j,k}^{W}(p(\xi)). \tag{13}$$

In fact, Eq. (12) can be rewritten as:

$$X(\xi(\theta) \in [a, b]) = X_0 + \sum_{j=0}^{\infty} \sum_{k=0}^{2^{j}-1} X_{j,k}^{w} \psi_{j,k}^{w}(\mathbf{p}(\xi)), \tag{14}$$

where  $X_0 \equiv P^0 X(\xi)$ . Moreover, the ortho-normality of the Haar wavelets ensures that

$$\int_{[a,b]} W_{j,k}(\xi) W_{l,m}(\xi) \operatorname{pdf}(\xi) d\xi = \int_{0}^{1} \psi_{j,k}^{W}(y) \psi_{l,m}^{W}(y) dy \equiv \delta_{j,l} \delta_{k,m}.$$
(15)

This shows that the set of wavelets  $\{W_{j,k}, j=0,\ldots,\infty; k=0,\ldots,2^{j}-1\}$  forms an orthonormal system with respect to the inner product:

$$\langle f, g \rangle \equiv \int_{[a,b]} f(\xi)g(\xi)\operatorname{pdf}(\xi)d\xi,$$

and that  $\langle f \rangle$  coincides with the mean or expectation.

Let us denote by  $\nabla$  the set of index integers  $\lambda$  concatenating the scale index j and the space index k:  $\nabla \equiv \{\lambda : \lambda = 2^j + k; j = 0, \dots, \infty; k = 0, \dots, 2^j - 1\}$ . The resolution level will be denoted by  $|\lambda|$ . Using these conventions, the one-dimensional wavelet expansion of  $X(\theta)$  can be expressed as:

$$X(\xi(\theta) \in [a, b]) = X_0 + \sum_{\lambda \in \nabla} X_{\lambda} W_{\lambda}(\xi(\theta)).$$
(16)

Moreover,

$$X_{0} \equiv \int_{0}^{1} X(\mathbf{p}^{-1}(y)) \phi_{0,0}^{\mathbf{w}}(y) dy = \int_{[a,b]} X(\xi) \mathbf{p} df(\xi) dy = \langle X(\xi) \rangle, \qquad (17)$$

is the expected value of the process. Consequently, setting  $W_0 \equiv 1$ , and denoting  $\nabla_0$  the extension of  $\nabla$  to include the index 0, the 1-D wavelet expansion becomes:

$$X(\xi(\theta) \in [a, b]) = \sum_{\lambda \in \nabla_0} X_{\lambda} W_{\lambda}(\xi(\theta)).$$
(18)

where

$$X_{\lambda} \equiv \int_{0}^{1} X(\mathbf{p}^{-1}(y)) \psi_{\lambda}^{\mathbf{w}}(y) dy$$
$$= \int_{[a,b]} X(\xi) \mathbf{W}_{\lambda}(\xi) \mathbf{p} df(\xi) d\xi = \langle X(\xi) \mathbf{W}_{\lambda}(\xi) \rangle.$$
(19)

This expansion is the wavelet analogue of the classical PC expansion used in stochastic spectral methods.

#### 2.3 Multidimensional process

In this section, we extend the WHa expansion to the multidimensional case, and focus for simplicity on a vector  $\xi$  of random components  $\{\xi_1(\theta), \ldots, \xi_N(\theta)\}$  obeying:

$$\langle \xi_i \rangle = 0, \quad i = 1, \dots, N \langle \xi_i \xi_j \rangle = \langle \xi_i^2 \rangle \delta_{ij}, \quad 1 \le i, j \le N.$$

We now consider the multi-dimensional index  $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_N)$ , and define the sequence

$$\mathcal{W}_n \equiv \left\{\prod_{k=1}^N \mathcal{W}_{\lambda_k}(\xi_k) : \sum_{k=1}^N |\lambda_k| = n 
ight\}$$

be the set of multidimensional wavelets having resolution n. The multidimensional wavelet expansion of  $X(\theta)$  can now be formally written as [1,8]:

$$X(\xi_{1}(\theta), \dots, \xi_{N}(\theta)) = X_{0} \mathcal{W}_{0} + \sum_{i_{1}=1}^{N} c_{i_{1}} \Gamma_{1}(\xi_{i_{1}}(\theta))$$

$$+ \sum_{i_{1}=1}^{N} \sum_{i_{2}=1}^{i_{1}} c_{i_{1}i_{2}} \Gamma_{2}(\xi_{i_{1}}(\theta), \xi_{i_{2}}(\theta))$$

$$+ \sum_{i_{1}=1}^{N} \sum_{i_{2}=1}^{i_{1}} \sum_{i_{3}=1}^{i_{2}} c_{i_{1}i_{2}i_{3}} \Gamma_{3}(\xi_{i_{1}}(\theta), \xi_{i_{2}}(\theta)\xi_{i_{3}}(\theta)) + \dots$$
 (20)

where  $\Gamma_0(\xi) \equiv 1$ , and  $\Gamma_k \in \mathcal{W}_k$  denotes a multidimensional wavelet of resolution k. In partice, the wavelet expansion must be truncated, and different strategies may be used for this purpose. The most intuitive approach is to retain wavelets of resolution n, i.e. we retain vectors  $\boldsymbol{\lambda}$  such that  $\sum_{k=1}^N |\lambda_k| \leq n$ . In this case, the multi-dimensional resolution level n plays a similar role as the order in Wiener-Hermite expansions [1,8]. Another possibility is to use the "spherical truncation", e.g. by retaining vectors  $\boldsymbol{\lambda}$  satisfying  $\left(\sum_{k=1}^N |\lambda_k|^2\right)^{1/2} \leq n$ .

Regardless of the truncation strategy, the truncated expansion may be conveniently rewritten as a single-index summation, according to:

$$X(\xi) \approx \sum_{k=0}^{N_w} X_k^{\mathrm{w}} \mathcal{H} a_k(\xi(\theta)), \tag{21}$$

where  $N_w + 1$  is the dimension of the truncated basis,  $\{\mathcal{H}a_k, k = 0, \dots, N_w\}$ .

## 2.4 Comparison with spectral expansions

Similar to the WHe [1,8] and other spectral representations [20], the wavelet expansion (Eq. 21) is an orthonormal approximation of the stochastic process. This property may be immediately exploited to extract the process expectation,

$$< X > = X_0^{\text{w}},$$

and its variance

$$\sigma^2(X) = \sum_{k=1}^{N_w} (X_k^{\mathrm{w}})^2.$$

Despite, the formal similarities of the expansion, fundamental differences between wavelet and spectral representations should be noted. In the latter case, global orthogonal polynomials are specifically selected so that, when appropriate smoothness conditions are satisfied, an "infinite-order" convergence rate results. Such convergence rate is not expected for the WHa expansion, in which the basis are localized. Specifically, the WHa expansion derived above can be viewed as an "orthogonal sampling" or a local decomposition of the solution into piece-wise constant processes. One may expect that in situations where the response of the system shows a localized sharp variation or a discontinuous change, the wavelet decomposition may be more efficient than a spectral expansions, whose convergence could dramatically deteriorate due to Gibbstype phenomena. Another distinctive feature of the WHa expansion concerns products of piecewise constant processes. For instance, the product xy of two elements x and y of  $V_j$  also belong to the same space. In contrast, the product

of two polynomials of degree less or equal to n does not necessarily belong to the space of polynomials having degree less or equal to n. Thus, one may also expect that for stiff the WHa scheme is less susceptible to aliasing errors than a spectral scheme. Below, we address these questions by considering situations involving both smooth and discontinuous dependence on the random data, and contrast the behavior of WHa and WLe expansions.

## 3 Model Problem

We first apply the WHa decomposition to a simple model problem that involves a discontinuous dependence of the process on the random data. This provides a stringent test of the representation, as one expects that a global spectral expansion would exhibit severe difficulties in capturing the behavior of the stochastic process. To this end, results obtained using the WHa expansion are contrasted with spectral results based on a WLe representation.

#### 3.1 Problem statement

Consider the following deterministic differential equation,

$$\frac{d^2x}{dt^2} + f\frac{dx}{dt} = -\frac{dh}{dx},\tag{22}$$

with specific parameters f > 0 and dh/dx. The problem requires two initial conditions:  $x(t=0) = x_0$  and  $v(t=0) \equiv dx/dt(t=0) = v_0$ . The system can be interpreted as the governing equation for a particle moving under the influence of a potential field and of a friction force. In the computations below, we set  $h(x) = \frac{35}{8}x^4 - \frac{15}{4}x^2$  so that the differential equation has two stable fixed points  $(x = \pm \sqrt{15/35})$ , and an unstable fixed point at x=0. he function h(x) and the potential field dh/dx are plotted in Fig. 1.

A stochastic variant of the above system is constructed by considering an initial position  $x_0$ . On the other hand, the particle is always released with a vanishing velocity. In the computations, we assume that the initial position is uniformly distributed over the interval  $[x_1, x_2]$ , i.e.  $pdf(x_0 \in [x_1, x_2]) = 1/|x_2 - x_1|$  and  $\int_{x_1}^{x_2} pdf(x)dx = 1$ . The stochastic initial conditions can be expressed as:

$$X(t=0,\xi) = X_0 + \Delta X \xi, \quad \frac{dX}{dt}\Big|_{t=0} = 0,$$

where  $X(t,\xi)$  denotes the response of the stochastic system,  $X_0 \equiv (x_1+x_2)/2$ ,  $\Delta X = |x_1-x_2|/2$ , and  $\xi$  is uniformly distributed over [-1,1] with pdf $(\xi) = 1/2$ . Thus, the stochastic system can be formulated as:

$$\frac{d^2X}{dt^2} + f\frac{dX}{dt} = -\frac{35}{2}X^3 - \frac{15}{2}X\tag{23}$$

$$X(t=0,\xi) = X_0 + \Delta X \xi \tag{24}$$

$$\left. \frac{dX}{dt} \right|_{t=0} = 0 \tag{25}$$

#### 3.1.1 Solution method

In this section, we outline the method used to integrate the stochastic formulation based on the WHa representation. The solution method for the WLe representation is similar and is consequently omitted.

The truncated WHa expansion of the solution process is expressed as:

$$X(t, \xi(\theta)) \approx \tilde{X}(t, \xi) = \sum_{k=0}^{N_w} X_k^{\mathrm{w}}(t) \mathcal{H} a_k(\xi).$$

Governing equations for the wavelet coefficients  $X_k^{\text{w}}$  are derived in two steps. The truncated wavelet expansion is first inserted into Eq. 23, and projections onto the wavelet basis are then performed. The latter step is implemented by multiplying the expanded system by  $\mathcal{H}a_l$  and then forming the expectation. This results in a system of  $N_w + 1$  coupled problem ode's for the coefficients:

$$\frac{d^2 X_l^{\mathrm{w}}}{dt^2} + f \frac{dX_l^{\mathrm{w}}}{dt} = -\frac{35}{2} \left\langle \tilde{X}^3 \mathcal{H} a_l \right\rangle - \frac{15}{2} X_l^{\mathrm{w}}, \tag{26}$$

for  $l = 0, ..., N_w$ . A similar Galerkin approach is used to derive initial conditions for the individual modes; we get:

$$X_0^{\mathrm{w}}(t=0) = X_0; \quad X_l^{\mathrm{w}}(t=0) = \Delta X \langle \xi \mathcal{H} a_l \rangle \quad \text{for } l = 1, \dots, N_w$$
 (27)

$$\left. \frac{dX_l^{\mathbf{w}}}{dt} \right|_{t=0} = 0 \quad \text{for } l = 0, \dots, N_w$$
 (28)

Equation (26) can be easily integrated once the projection of the cubic, non-linear term is determined. To this end, let  $C_{ijk}$  denote the multiplication tensor,

$$C_{ijk} \equiv \langle \mathcal{H} a_i \mathcal{H} a_j \mathcal{H} a_k \rangle$$
.

One can immediately [8, 12, 13] show that the quadratic term  $X^2$  can be obtained from:

$$(X^2)_k^{\mathbf{w}} \equiv \left\langle \tilde{X}^2 \mathcal{H} a_k \right\rangle = \sum_{i=0}^{N_w} \sum_{j=0}^{N_w} C_{ijk} X_i^{\mathbf{w}} X_j^{\mathbf{w}}.$$

The wavelet expansion of the cubic term is then obtained by a second application of the binary multiplication operator, namely

$$(X^3)_k^{\mathbf{w}} \equiv \left\langle (X^3) \mathcal{H} a_k \right\rangle = \left\langle (X) (X^2) \mathcal{H} a_k \right\rangle = \sum_{i=0}^{N_w} \sum_{j=0}^{N_w} C_{ijk} X_i^{\mathbf{w}} (X^2)_j^{\mathbf{w}}.$$

The same approach is used in the case of a Legendre expansion, i.e. the cubic term is obtained by repeated application of the corresponding binary multiplication operator [18,21]. Note, however, that in the case of the WHa expansion, the factorization approach leads to an exact Galerkin estimate of the cubic term. This is the case because, as previously noted, the product of elements of  $V_j$  also belongs to  $V_j$ . For the WLe and other polynomial representations, on the other hand, repeated binary products introduce aliasing errors. In this case, the procedure is referred to as "pseudo-spectral," in order to distinguish it from the pure Galerkin case [18,21].

The multiplication tensor  $C_{ijk}$  is evaluated in a pre-processing and then stored for later use. This evaluation, as well as several useful transformations, such as products and inverse transformations, are implemented using a software library of routines which we call the UQ toolkit. This library was initially developed for Wiener-Hermite representations [18, 21], but was extended to include the presently considered expansions. Note that, similar to the Hermite and Legendre systems, the multiplication tensor in the Haar system is sparse and can be evaluated exactly. Moreover, in the latter case, the evaluation can be performed in a more efficient fashion, since it only involves integer operations.

The time integration of Eq. 26 is performed using a fourth-order Runge-Kutta scheme. In all computations described in this section, a small value of the time step was used,  $\Delta t = 0.001$ . This value was selected following a straightforward analysis in which the time step was systematically reduced until it had negligible impact on the predictions.

Below, we compare solutions obtained using the WHa expansion, truncated to a given resolution level Nr, with results obtained using a WLe expansion, truncated to order No. Since we are dealing with a single stochastic dimension, the total number of basis functions equals in WHa expansion is equal to  $2^{Nr}$ ; in the case of WLe, it is equal to No + 1.

#### 3.2.1 WLe scheme

The WLe scheme is applied to the model problem above, with stochastic initial conditions specified by  $X_0 = 0.05$  and  $\Delta X = 0.2$ . A relatively large value of the friction coefficient is selected, f = 2, so that a steady solution is achieved in a short time. For the present conditions, the analytical predictions of the steady state is given by:

$$\begin{cases} X(t \to \infty, \xi) = -\sqrt{15/35} \ \xi < -0.25 \\ X(t \to \infty, \xi) = \sqrt{15/35} \ \xi > -0.25 \end{cases}.$$

which results in the following statistical moments,  $\langle X(t \to \infty, \theta) \rangle = 0.1636634$  and  $\sigma(t \to \infty, \theta) \rangle = 0.633865691$ .

Figure 2 depicts WLe solutions for different expansion orders. Plotted are the short-time evolution of  $X(t,\xi)$ , the "large-time" steady solution, and the corresponding pdf of X. The results indicate that, regardless of the order of expansion, the WLe scheme does not provide an adequate representation of the system. Specifically, unphysical oscillations in the steady distribution of  $X(\xi)$  are observed. Around the equilibrium point  $X=\sqrt{15/35}$ , the amplitude of the wiggles decreases slightly as No increases, but their frequency increases, which are only slowly damped as No increases. The manifestation of these wiggles is reminiscent of Gibbs type phenomena which occur in spectral decompositions of discontinuous signals. The impact of this phenomenon can be clearly appreciated in the predicted steady-state pdf of X, shown in the right column of Fig. 2. For the present stochastic problem, the analytical pdf consists of two Dirac masses of unequal strength, located at the stable equilibrium points  $X = \pm \sqrt{15/35}$ . The WLe predictions differ significantly from the analytical prediction; around the equilibrium points, they exhibit a broad spectrum with multiple peaks. This phenomenon is also characteristic of the application of a spectral representation to a discountinuous problem.

In addition to poor representation of the process pdf, in the present case the WLe scheme also fails to provide accurate predictions of some of the low-order moments. To illustrate this claim, Table 1 shows the WLe predictions of the mean and standard deviation of X at steady state. The results demonstrate that the mean response is poorly estimated and that it fluctuates substantially with No. Better, though still inadequate, predictions of the standard deviation are obtained. However, similar to the mean, these predictions also fluctuate with No.

No	$< X(\theta) >$	$\sigma(X(\theta))$
3	$8.37 \ 10^{-6}$	0.6546
5	0.000324	0.6543
7	0.250818	0.6047
9	0.201684	0.6228
11	0.169491	0.6324
15	0.127727	0.6420

Table 1

Mean and standard deviation of X at steady state. Results are obtained with the WLe scheme with different No. The analytical predictions are given by  $\langle X(\theta) \rangle = 0.16366$  and  $\sigma(X(\theta)) = 0.63387$ .

#### 3.2.2 WHa scheme

The WHa scheme is now applied to the same problem of section 3.2.1. Results are obtained for an increasing number Nr of resolution levels. Figure 3 shows the evolution of  $X(t,\xi)$  for  $0 \le t \le 10$ ; results obtained with Nr = 2, 3, 4 and 5 are depicted. The results indicate that, so long as Nr > 2, the WHa scheme correctly captures the bifurcation dividing the trajectories converging to the two stable equilibrium points. The transition is first captured at Nr=3 and further increase of the value of Nr only affects the smoothness of the solution during the initial transient. For Nr=2, the WHa scheme yields an incorrect result for  $-0.5 < \xi < 0$ , predicting in this range that the position rapidly equilibrates at X=0. This corresponds to a physical but unstable equilibrium point. This erroneous prediction is obtained because the mean initial position over the corresponding uncertainty range is zero. It is interesting to note that, although the prediction for Nr=2 is incorrect for  $-0.5 \le \xi \le 0$ , it is correct for the remaining parts of the uncertainty range. Thus, errors incurred for at specific values of the random data do not appear to pollute the entire prediction; this (desriable) of WHa schemes has been observed in a large number of (under-resolved) computations.

The mean and standard deviation of X at steady state are reported in Table 2 for all considered values of Nr. We observe that for  $Nr \geq 3$  the analytical prediction is exactly recovered. This complete agreement with the analytical solution is in the present case due to the fact that the discontinuity, located at  $\xi = -0.25$ , is "naturally" captured for  $Nr \geq 3$ ; it is specifically located at the edge of neighboring wavelets at the level j = 3. Thus, the steady-state solution has vanishing details for scales (or resolution indices) j > 3.

Nr	$< X(\theta) >$	$\sigma(X(\theta))$
2	0.3273268	0.566946718
3	0.1636634	0.633865691
4	0.1636634	0.633865691

Table 2

Mean and standard deviation of X at steady state. Results are obtained using the WHa scheme with different Nr. The analytical predictions are give by  $\langle X(\theta) \rangle = 0.1636634$  and  $\sigma(X(\theta)) = 0.633865691$ .

#### 3.2.3 Highly discontinuous solution

The example above showed that in the case of a single point of discontinuity, the WHa decomposition can provide an accurate representation of the stochastic process, but that the WLe scheme proved inadequate. To have a finer appreciation of the properties of the WHa scheme, we now consider a more difficult problem obtained simply by reducing the friction coefficient, f. Specifically, we set f = 0.05 and focus on stochastic initial conditions given by  $X_0 = 1$  and  $\Delta X = 0.1$ . As in the previous case, the particle is released from a state of rest, i.e. the initial velocity is deterministic and equal to 0.

The reduction of the friction coefficient, together with the higher initial energy of the system, result in a complex response. Specifically, the particle oscillates for several cycles between the two potential wells, before reaching a final equilibrium position. Furthermore, the inverse map between each of two stable equilibrium points and the corresponding initial positions (which as previously mentioned is assumed to be uniformly distributed between 0.9 and 1.1), results in a union of several disjoint intervals. Thus, the situation is more complex than that of the previous problems, where two intervals were obtained. Consequently, one anticipates that a significantly higher resolution level would be needed to correctly characterize the behavior of the stochastic system.

To illustrate the convergence of the WHa scheme in the present case, results were obtained with a wider range of resolution levels,  $3 \leq Nr \leq 8$ . Results are plotted in Fig. 4, which depicts  $X(\xi)$  at t=100 for all considered values of Nr. The results indicate that for the present conditions, 6 resolution levels are needed to capture the response of the system, and particularly all the corresponding discontinuities. By increasing the resolution level beyond Nr=6, one obtains additional details on the response of the system with region of continuity, as well as a slight refinement of the locations of the discontinuities.

One also notes that, even when the resolution level is too low to correctly capture all of the discontinuities, the WHa expansion still provides a meaningful prediction, in the sense steady local realization do in fact corresponding to a

stable equilibrium point. In other words, resolution errors do not in the present case lead to an unphysical prediction. This robustness of the WHa expansion is further illustrated in Fig. 5 which compares the WHa solution using Nr=7with the WLe prediction with No = 32. The results are generated at t = 250, where a stationary state is nearly reached. The figure shows that the WLe prediction is everywhere polluted by wiggles and yields predictions that are far from true equilibrium. With the WHa scheme, on the other hand, the correct result is obtained. Naturally, the robustness of the WHa predicitions should be carefully exploited, so as to ensure that the process is adequately resolved and that statistical moments are accurately computed. This can be achieved by systematic refinement of resolution level, as performed in the example above.

## Application to Rayleigh-Bénard Instability

In the previous section, a simple model problem was considered whose motion is governed by a simple ode. In this section, we address a more complex problem that consists of a stochastic Rayleigh-Bénard flow with random data in the neighborhood of the critical point. Specifically, we consider a closed rectangular 2D cavity of height H and length L that is filled with a Newtonian fluid. Gravity points downwards, and the bottom wall of the cavity is maintained at a hot temperature  $T_{\text{hot}}$  while the top wall is maintained at a cold temperature  $T_{\text{cold}}$ . The vertical thermal gradient can also be characterized in terms of the reference temperature  $T_{\rm ref} \equiv (T_{\rm hot} + T_{\rm cold})/2$ , and the temperature difference  $\Delta T \equiv T_{\rm hot} - T_{\rm cold}$ . The vertical walls are assumed adiabatic.

#### Deterministic System

Assuming that the temperature is difference small, i.e.  $\Delta T/T_{\rm ref} \ll 1$ , the Boussinesq approximation is invoked. Thus, for deterministic conditions the flow is governed by the following system of normalized equations [22, 23]:

$$\nabla \cdot \boldsymbol{u} = 0, \tag{29}$$

$$\nabla \cdot \boldsymbol{u} = 0,$$

$$\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u} \cdot \nabla \boldsymbol{u} = -\nabla p + \frac{\Pr}{\sqrt{\operatorname{Ra}}} \nabla^2 \boldsymbol{u} + \Pr \Theta \boldsymbol{y},$$
(30)

$$\frac{\partial \Theta}{\partial t} + \nabla \cdot (\boldsymbol{u}\Theta) = \frac{1}{\sqrt{Ra}} \nabla^2 \Theta. \tag{31}$$

where  $\boldsymbol{u}$  is the velocity, p is pressure, t is time, and  $\Theta \equiv \frac{T-T_{\rm ref}}{\Delta T}$  is the scaled temperature. The system involves two dimensionless parameters, namely the Prandtl number  $\Pr \equiv \frac{\mu C_p}{\kappa}$ , and the Rayleigh number  $\operatorname{Ra} \equiv \frac{\rho g \beta \Delta T H^3}{\mu \kappa}$ . Here,  $\mu$  is the viscosity,  $C_p$  is the heat capacity,  $\kappa$  is the thermal conductivity,  $\rho$  is the density, g is gravity, and  $\beta$  is the coefficient of thermal expansion.

Let  $\Omega$  denote the computational domain,  $\partial\Omega$  its boundary. We denote by  $\partial\Omega_c$  the cold wall,  $\partial\Omega_h$  the hot wall, and  $\partial Omega_v$  the vertical walls; we have  $\partial\Omega = \partial\Omega_h \cup \partial\Omega_c \cup \partial\Omega_v$ . Using this notation, the boundary conditions are expressed as:

$$\boldsymbol{u}(\boldsymbol{x},t) = 0 \ \forall \boldsymbol{x} \in \partial\Omega, \quad \Theta(\boldsymbol{x},t) \equiv \Theta_{h} = \frac{1}{2} \forall \boldsymbol{x} \in \partial\Omega_{h},$$
 (32)

$$\Theta(\boldsymbol{x},t) \equiv \Theta_{c} = -\frac{1}{2} \forall \boldsymbol{x} \in \partial \Omega_{c}, \quad \frac{\partial \Theta(\boldsymbol{x},t)}{\partial x} = 0 \forall \boldsymbol{x} \in \partial \Omega_{v}, \tag{33}$$

The stability of the Rayleigh-Bénard problem summarized above has been extensively analyzed. In particular, results [24, 25] reveal the existence of a critical value of  $Ra_c$  of the Rayleigh number, below which the flow is stable. In this regime, the fluid velocity vanishes identically, and the temperature distribution exhibits a linear variation vertically across the cavity, which is representative of a purely conductive system. Above the critical value, the flow is unstable and the growth of the instability leads to the establishment of recirculation zones, which results in enhanced heat transfer across the cavity.

Below, we address a stochastic variant of the Rayleigh-Bénard problem, focusing on the case of random parameter which can result in either stable or unstable flow behavior. Thus, the presence of the bifurcation provides a significant challenge to the computations. Below, we address this question by applying both the WLe and WHa expansions to the case of cavity with aspect ration  $A \equiv L/H = 2$ , filled with air (Pr = 0.7), under deterministic cold-wall temperature  $T_c$  but random hot-wall temperature  $T_h$ . The statistics of  $T_h$  are assumed to be such that both stable and unstable behavior occur with finite probability.

#### 4.2 Stochastic Formulation

As mentioned above, the hot-wall temperature is now considered to be random. We model the uncertainty by decomposing  $\Theta_h$  as  $\Theta_h(\theta) \equiv \Theta_h(\xi(\theta)) = \frac{1}{2} + \Theta_r \xi(\theta)$ . (In the stochastic case, the quantities  $\Delta T$  and  $T_{\text{ref}}$  are defined using the mean hot wall temperature,  $\langle T_h \rangle$ .) Thus,  $\Theta_r$  characterizes the random fluctuations around the mean. The random variable  $\xi$  is assumed to be uniformly distributed on the interval [-1,1].

Similar to the approach of the previous section, both the WLe and WHa expansions are implemented. Thus, in ther former case the solution is repre-

sented in terms of Legendre polynomials  $\mathcal{L}e_k$ , and in the latter in terms of Haar wavelets,  $\mathcal{H}a_k$ . However, since the numerical treatment is independent of the selected basis, we shall derive the governing equations in terms of the a generic basis  $\Psi_k$ ,  $k = 0, \ldots, P$  where P + 1 is the dimension of the basis and  $\Psi_k$  denotes either  $\mathcal{L}e_k$  or  $\mathcal{H}a_k$ . Using this notation, the uncertain velocity, pressure and temperature fields are expanded as:

$$\boldsymbol{u}(\boldsymbol{x},t,\xi) = \sum_{k=0}^{P} \Psi_k(\xi) \boldsymbol{u}_k(\boldsymbol{x},t), \tag{34}$$

$$p(\boldsymbol{x}, t, \xi) = \sum_{k=0}^{P} \Psi_k(\xi) p_k(\boldsymbol{x}, t), \tag{35}$$

$$\Theta(\boldsymbol{x}, t, \xi) = \sum_{k=0}^{P} \Psi_k(\xi) \Theta_k(\boldsymbol{x}, t).$$
(36)

Governing equations for the unknown coefficients are obtained by introducing these expansions into the governing equations, multiplying the result by  $\Psi_i$  and evaluating the expectation. Exploiting the orthogonality of the basis, we obtain the following coupled system [12, 13]:

$$\nabla \cdot \boldsymbol{u}_i = 0, \tag{37}$$

$$\frac{\partial \boldsymbol{u}_{i}}{\partial t} + \sum_{i=0}^{P} \sum_{k=0}^{l} \mathcal{M}_{ijk} \boldsymbol{u}_{j} \cdot \boldsymbol{\nabla} \boldsymbol{u}_{k} = -\boldsymbol{\nabla} p_{i} + \frac{\Pr}{\sqrt{\operatorname{Ra}}} \boldsymbol{\nabla}^{2} \boldsymbol{u}_{i} + \Pr\Theta_{i} \boldsymbol{y}, \tag{38}$$

$$\frac{\partial \Theta_i}{\partial t} + \sum_{j=0}^{P} \sum_{k=0}^{l} \mathcal{M}_{ijk} \nabla \cdot (\boldsymbol{u}_j \Theta_k) = \frac{1}{\sqrt{\text{Ra}}} \nabla^2 \Theta_i.$$
 (39)

for i = 0, ..., P. Here,  $\mathcal{M}$  the multiplication tensor given by:

$${\cal M}_{ilm} = {\cal M}_{iml} \equiv rac{\langle \Psi_i \Psi_j \Psi_k 
angle}{\langle \Psi_i \Psi_i 
angle}$$

Velocity boundary conditions on  $\partial\Omega$  are  $\boldsymbol{u}_i=0$  for  $i=0,\ldots,P$ . For the scaled temperature, we have:

$$\Theta_0 = -\frac{1}{2}, \quad \Theta_{i=1,\dots,P} = 0 \quad \forall \boldsymbol{x} \in \partial \Omega_e$$
(40)

$$\Theta_i = \frac{\langle \Theta_{h}(\xi) \Psi_i(\xi) \rangle}{\langle \Psi_i \Psi_i \rangle} \text{ for } i = 0, \dots, P \quad \forall \boldsymbol{x} \in \partial \Omega_h$$
(41)

$$\frac{\partial \Theta_i}{\partial x} = 0 \text{ for } i = 0, \dots, P \quad \forall \boldsymbol{x} \in \partial \Omega_v$$
 (42)

The governing equations (37-39) are integrated using the stochastic projection method (SPM) described in [13]. The method is relies on a second-order, conservative, finite-difference discretization of field variables. Velocities are discretized on cell edges, while pressure and temperature are discritized at cell centers. Evolution equations are integrated in time using a second-order, explicit, predictor-corrector scheme [26]. Enforcement of velocity divergence constraints are efficiently implemented using a pressure correction step, which involves the solution of a system of decoupled pressure Poisson equations [12]. The present construction generalizes the scheme developed in [13], primarily by the incorporation of a higher-order integration scheme and of an extended formulation that adapts the multiplication tensor to the selected basis function expansion.

Prior to performing stochastic simulations, deterministic computations were performed (simply by setting P=0). We set Ra = 2150, i.e. the Rayleigh number is slightly larger than critical. The simulations were then performed by perturbing the hot wall temperature so as to determine the critical conditions for the instability. In these computations, the initial condition consists of the purely conductive solution, which is perturbed using a low-energy white-noise perturbation. As illustrated in Fig. 6, after a short time the kinetic energy exhibits an exponential growth or decay, depending on the (perturbed) value of the hot wall temperature. The critical temperature is determined by computing the growth rate for different values of  $\Theta_h$ , as shown in Fig. 6. The curve is then interpolated in order to locate the value where the growth rate vanishes. The results indicate that, for the present parameters, a critical value  $\tilde{\Theta}_h = 0.4301$  is obtained.

Consequently, for the presently selected conditions, the overall heat transfer corresponds to the purely conductive solution whenever  $\Theta_h \leq \tilde{\Theta}_h$ . The rate of heat transfer is characterized using the Nusselt number:

$$\mathrm{Nu} \equiv \frac{1}{A(\Theta_{\mathrm{h}} - \Theta_{\mathrm{c}})} \int_{0}^{A} \frac{\partial \Theta}{\partial y} \bigg|_{y=0} dx.$$

Clearly, in the stable (conductive) regime, Nu = 1. For  $\Theta_h > \tilde{\Theta}_h$ , heat transfer enhancement occurs so that  $Nu(\Theta_h) > 1$ . Thus, the difference  $\delta Nu(\Theta_h) \equiv Nu(\Theta_h) - 1$  provides a measure of the heat transfer enhancement.

In this section, we apply the WLe scheme to simulate the response of the stochastic flow. As mentioned earlier, we focus on the case of uncertain hot wall temperature, which is assumed to be uniformly distributed in the range [0.3, 0.5]. Following the discussion above, both a stable and an unstable flow behavior occur for this uncertainty range.

Figure 7 kinetic energy as a function of  $\Theta_h$  for different values of No. The curves are reconstructed from the steady-state WLe coefficients. The results show indicate the curves approach each other as No increases, which suggests that the WLe computations are converging. Unfortunately, individual realizations obtained for  $\Theta_h < \tilde{\Theta}_h$  do not exhbit a vanishing kinetic energy, as one would expect based on the stability considerations above. In other words, if the WLe computations are in fact converging, they do not appear to be converging to the exact solution.

In order to gain additional insight into the behavior of WLe predictions, we plot in Fig. 8 curves for  $\delta Nu$  as function of  $\Theta_h(\xi)$ . As before; results are generated for different expansion orders, No. As for the kinetic energy, the observed behavior of  $\delta Nu$  appears to converge with increasing No, but not the exact solution. Furthermore, at low values of  $\Theta_h$ , an unphysical effect, corresponding to negative values of  $\delta Nu$ , can be observed. Specifically, the negative values of  $\delta$ Nu indicate that, for the corresponding realizations, an overall heat transfer rate is predicted that is *smaller* than that of the conductive solution! This unphysical response occurs over a substantial band of possible realizations, which extends over about 25% of the entire range of possible realizations. The origin of the unphysical response is further analyzed in Fig. 9, which shows the steady-state velocity and temperature fields (reconstructed from the WLe expansion) for selected values of  $\Theta_h$ . In particular, the figure shows that for sub-critical values of  $\Theta_h$ , instead of vanishing the predicted velocity exhibits a recirculating flow pattern with a reverse sign. Thus, the "energy leakage" that was earlier observed in Fig. 7 for small  $\Theta_h$ , is accompanied by a severe breakdown of the WLe prediction.

Figure 10 shows pdf of  $\delta$ Nu for WLe expansion with No=3, 5, 7 and 9. The results illustrate the difficulties of the computations in approaching the exact solution, which should exhibit a singular spike at  $\delta$ Nu = 0. Another symptom of the inefficiency of the WLe expansion for the present problem is the loss of spectral convergence. This can be appreciated from Table 3, which provides the mean values of overall heat transfer rate,  $\langle \int_0^A \partial\Theta/\partial y dx \rangle$ , and of the corresponding standard deviation for different No.

The present experiences indicate that for problems involving bifurcations or

loss of smoothness with respect to the random data, the WLe expansion may be essentially impractical. Similar limitations for other spectral representations [20] based on global basis functions.

No	$\left\langle \int_0^{\mathrm{A}} \partial\Theta/\partial y dx \right\rangle$	Standard deviation
1	2.24405	0.4750
3	2.23657	0.4667
5	2.23929	0.4647
7	2.24254	0.4619

Table 3

Mean and standard deviation of the overall heat transfer rate across the cavity. Shown are results obtained using the WLe expansion with different expansion order, No.

## 4.4 WHa expansion

In this section, we apply the WHa scheme to compute the stochastic, steadystate response of the Rayleigh-Béndard flow. We use the same parameters as in the previous section, i.e. we focus on the case of uncertain hot wall temperature. We start by examining global properties of the flow field, and then analyze stochastic velocity and temperature distributions.

## 4.4.1 Kinetic energy and heat transfer

Figure 11 provides curves of the kinetic energy and  $\delta Nu$  plotted against  $\Theta_h$ . The curves are reconstructed based on the wavelet coefficients, and results are shown for expansion using Nr = 2, 3, 4 and 5. As far as these integral measures are concerned, the results indicate that the WHa scheme is much better adapted than the WLe scheme at capturing the transition between conductive and convective regimes, even when a coarse stochastic discretization with Nr = 2 is considered. As Nr increases, the computations provide an increasingly accurate estimate of the location of the critical point, as illustrated in Fig. 12. The latter provides an enlarged view of the local behavior of  $\delta Nu(\Theta)$  near the critical point, as well as the dependence of  $\delta Nu$  on  $\xi$ . In the latter format, the results illustrate the piecewise constant nature of the WHa expansion, as well as the essential concept of the approximation scheme which relies on projecting the solution onto the space  $V^{Nr}$ . The robustness of the WHa expansion in capturing the bifurcation can be appreciated by noting that the reconstructed curves capture the correct behavior on both sides of the critical point. Specifically, as predicted by the theory and confirmed by the perturbation analysis above, vanishing values of the kinetic energy and of  $\delta$ Nu are predicted for subcritical values of  $\Theta_h$ , while for supercritical values, an essentially linear increase of  $\delta$ Nu with  $\Theta_h$  is observed.

To gain further appreciation of the robustness of the WHa scheme, Table 4 provides the mean values of the overall heat transfer rate,  $\langle \int_0^{\mathbf{A}} \partial \Theta / \partial y dx \rangle$ , and of the corresponding standard deviation for different Nr. The results indicate that the predictions are close to one another and tend to cluster as Nr increases.

$\overline{Nr}$	$\left\langle \int_0^{\mathbf{A}} \partial\Theta/\partial y dx \right\rangle$	Standard deviation
1	2.22300	0.4230
2	2.23588	0.4524
3	2.23791	0.4627
4	2.23795	0.4653
5	2.23906	0.4652

Table 4

Mean and standard deviation of the overall heat transfer rate across the cavity. Shown are results obtained using the WHa expansion with different resolution levels, Nr.

#### 4.4.2 Details distributions of velocity and temperature

Figure 13 shows the computed velocity fields corresponding to the detail coefficients. Recall that for the present 1D WHa expansion, the velocity is expressed in terms of the details  $u_{j,k}$  according to:

$$oldsymbol{u}(oldsymbol{x}, \xi) = \sum_{k=0}^{2^{Nr}-1} oldsymbol{u}_k(oldsymbol{x}) \mathcal{H} a_k(\xi) \equiv oldsymbol{u}_0 + \sum_{j=1}^{Nr} \sum_{k=0}^{2^{j-1}-1} oldsymbol{u}_{j,k} \psi_{j,k}^{ ext{w}}( ext{p}(\xi)).$$

In the left column of Fig. 13, we show the mean field  $\mathbf{u}_0(\mathbf{x}) \equiv \langle \mathbf{u} \rangle$ ; in the second column, the detail corresponding to the difference of the mean with  $P^1\mathbf{u}$ . As expected, the latter indicates that the circulation inside the cavity increases with  $\xi$ , and accordingly with  $\Theta_h$ . The second detail fields, which are plotted in the third column, correspond to differences between  $P^2\mathbf{u}$  and  $P^1\mathbf{u}$ ; they reveal a similar recirculating pattern as the first detail and point to a similar trend. More interesting trends can be observed from the detail fields at the next level, j=3. Specifically, while the details corresponding to the highest values of  $\Theta_h$  (appearing on top) exhibits similar patterns and trends as those for j=2 and j=1, those corresponding to the low values have different structure. Specifically, for k=0, the field vanishes, indicating that no correction is needed for the corresponding "realizations". Furthermore, the detail for k=1 has larger magnitude than the other details at the same level; this increased "activity" coincides with the location of the transition

between conductive and convective regimes. On the next detail level, we again observe that no corrections are needed for the velocity fields at the lowest two temperature bands, whereas the corrections corresponding to the remaining fields reflect a trend of increasing circulation with higher temperatures. Similar trends can be observed by inspections of the details at the last level (j = 5), which are shown in Fig. 14.

The stochastic temperature field is analyzed following the same approach used for the velocity. In Fig. 15, we plot distributions of the mean velocity as well as the details for levels j = 1, 2, 3 and 4; details at the highest level, i = 5, are plotted in Fig. 16. Note that, unlike the velocity field, the detail distributions for temperature do not vanish, even at the highest resolution level. This is the case because inhomogeneous boundary prevail at the hot wall, regardless of whether the flow is stable or not. Nonetheless, the transition from a conductive to a convective regime can still be detected. In the former case, the distributions are characterized by parallel horizontal contour lines while severe distortions of this pattern occur as the flow transitions. As for the velocity field, the results indicate that the transition is first captured at j=3; at this level, the detail corresponding to k=0 exhibits flat horizontal contours, while the detail temperature fields for k > 0 exhibit a distorted pattern that is characteristic of a recirculating flow field. It is interesting to note that at higher levels (Figs. 15 and 16, the detail distributions corresponding to supercritical temperature values exhibit a similar spatial distribution. This suggests that in this situation the higher levels primarily introduce an amplitude correction to the prevailing recirculating flow.

#### 4.5 Continuous problem

The results of the previous sections demonstrate that the WHa expansion provides a robust and well-suited approach for analyzing stochastic processes involving bifurcations or discontinuous dependence on random data. On the other hand, when the process depends smoothly on the random data, spectral expansions are expected to be substantially more efficient than wavelet representations. Specifically, for spectral representations a fast, "infinite-order" convergence is expected, while for the Haar representation errors are expected to decay as the inverse of Nr.

We briefly illustrate the convergence of the WHa and WLe schemes for a problem involving a smooth dependence on the random data. To this end, we consider once again the same stochastic Rayleigh-Bénard problem, but increase the Rayleigh number to Ra=3000. For this value of the Rayleigh number, the convective regime always prevails as all possible realizations of  $\Theta_h$  are larger than the critical value.

Table 5 shows predictions of the mean overall heat transfer and of the corresponding standard deviation, using the WHa scheme with increasing Nrand the WLe scheme with increasing No. The results indicate that the WLe predictions rapidly become independent of No; in particular, identical predictions of the mean heat transfer and its standard deviation are obtained with No = 4 and 5. The WHa predictions also appear to be converging as Nrincreases, though at an appreciably smaller rate. To gain additional insight into the convergence of both predictions, we plot in Fig. 17 an approximate error estimate, defined as the absolute value of the difference between a given prediction and the WLe result with No = 5. Thus, in these estimates, the 5th-order WLe solution is used as surrogate for the exact solution. The results of Fig. 17 illustrate, the fast decay of the error for the WLe scheme. For the WHa scheme, the error also decays with increasing Nr, though at an appreciable smaller rate. The moderate rate of convergence of the WHa computations can also be appreciated in Fig. 18, which depicts the computed distributions of  $\delta Nu$  for different values of Nr. The results illustrate the "staircase" Haar approximation of the continuous curve expressing the dependence of  $\delta Nu$  on  $\Theta_h$  and on  $\xi$ . Thus, for the present conditions, the WLe scheme outperforms the WHa scheme.

$\overline{Nr}$	$\left\langle \int_0^{\mathrm{A}} \partial\Theta/\partial y dx \right\rangle$	Standard deviation
1	2.92239879	0.49257723
2	2.92350067	0.55054599
3	2.92377786	0.56409585
4	2.92384732	0.56743188
5	2.92386463	0.56826288
6	2.92386897	0.56847041
No	$\left\langle \int_0^{\mathrm{A}} \partial\Theta/\partial y dx \right\rangle$	Standard deviation
1	2.92384455	0.56871803
2	2.92387023	0.56854003
3	2.92387042	0.56853954
4	2.92387042	0.56853957
5	2.92387042	0.56853957

Table 5

Mean and standard deviation of the overall heat transfer rate across the cavity. Shown are results obtained using the WHa expansion with different resolution levels, Nr, and the WLe scheme with different values of No. The Rayleigh number Ra = 3000, and unstable conditions prevails for all possible realizations of the hot wall temperature.

## 5 Conclusions

In this paper, an uncertainty propagation scheme is constructed based on generalized PC representations. The scheme relies on an orthogonal representation of the dependence of the solution on random parameters. A spectral representation in terms of Legendre basis functions is considered, as well as an orthogonal decompositon using Haar wavelets. In both cases, the unknown coefficients in the expansion are evaluated using a Galerkin procedure, which results in coupled evolution equations for the stochastic modes. The behavior of the resulting schemes are analyzed in light of computations of a simple dynamical system, and of simulations of near critical Rayleigh-Bénard flow. In both cases, attention is focused on the case of a discontinuous dependence of the stochastic process on the random input data.

The model computations focused on the idealized case of a particle moving under the action of an imposed potential and friction. Randomness is introduced in the form of a stochastic initial position, with uniform probability between two specified bounds. Depending on the value of the friction coefficient, the random process admits single or multiple discontinuities. When a single discontinuity occurs, the steady behavior of the problem was characterized analytically, and the analytical solution is used to verify computed predictions. The results indicate that the WHa scheme is well adapted to the present situation, and that the steady-state analytical predictions are recovered when sufficient resolution is provided. In contrast, computations performed using a WLe expansion provided poor estimates of both low-order statistics and of individual realizations. The robust behavior of the WHa scheme was also verified in situations where the stochastic system admits multiple discontinuities with respect to the random data. As in the previous case, the results indicate that with sufficient resolution accurate estimates of the statistics and of individual realizations are obtained.

Simulations were then performed of near critical Rayleigh-Bénard flow. These computations were based on an extended version of the SPM constructed in [13]. Attention was focused on the case of uncertain hot wall temperature, selected so that both stable and unstable behavior are likely to occur. Similar to earlier experiences with the model dynamical system, the simulations indicate that the WHa scheme effectively captures the transition, as well as the statistics of the stochastic process. In contrast, the WLe expansion suffered from several limitations, including poor prediction of transition and of the state of the system, especially in the case of stable realizations. The WHa and WLe schemes were also applied in situations involving smooth dependence on the random data, which were selected such that recirculating flow is established for all realizations. In this situation, both schemes performed in a satisfactory fashion with the WLe scheme exhibited a superior convergence.

The present experiences point to a number of interesting extensions of the present approach, including hybrid formulations combining wavelets and spectral expansions, and adaptive wavelet formulations. These extensions, as well as generalizations to multiple stochastic dimensions, are currently being explored.

## Figure Captions

**Figure 1**: Profiles of h(x) and of dh/dx for the model problem of section 3.

**Figure 2**: WLe solution for the model problem of section 3.2.1. The left column shown the evolution of  $X(t,\xi)$  for  $0 \le t \le 10$ . The steady solution  $X(t \to \infty, \xi)$  is plotted in the middle column and the corresponding pdf is shown in the right column. Results are obtained for expansion orders No = 3, 5, 7, 9 and 11, arranged from top to bottom.

**Figure 3**: WHa solution for the model problem of section 3.2.2. The plots show the evolution of  $X(t,\xi)$  for different resolution levels, Nr=2, 3, 4 and 6.

**Figure 4**: WHa solution at t = 100 for the model problem of section 3.2.3. The plots shown curves of  $X(t = 100, \xi)$  versus  $\xi$ , computed using different resolution levels, Nr = 3, 4, 5, 6, 7 and 8 as indicated.

**Figure 5**: Large-time (steady) solutions for the problem of section 3.2.3. Plotted are curves for  $X(t \to \infty, \xi)$  versus  $\xi$ . Left: WHa expansion with Nr = 6; right: WLe expansion with No = 32.

**Figure 6**: Left: Square root of kinetic energy versus time for the linearized Rayleigh-Bénard problem. Plotted are curves for different hot-wall temperatures. Right: linear growth rate versus hot-wall temperature. The critical value, determined by linear extrapolation, is  $\tilde{\Theta}_h = 0.4301$ . The computations were performed on a uniform mesh having having 60 grid points in the x-direction and 30 grid points in the y-direction.

**Figure 7**: Steady-state kinetic energy versus hot wall temperature using WLe expansions with No = 3, 5, 7, 9, 11 and 13. The right plot shows a detailed view in the neighborhood of the critical value.

**Figure 8**:  $\delta \text{Nu}(\Theta_h)$  versus  $\Theta_h$  using WLe expansions with No = 3, 5, 7, 9, 11 and 13. The right plot shows a detailed view in the neighborhood of the critical value.

**Figure 9**: Individual realizations of the steady-state temperature and velocity distributions, as predicted using a WLe expansion with No = 9. The selected values of  $\Theta_h$  are indicated. Due to symmetry with respect to the mid vertical plane, only the left half of the cavity is plotted.

- **Figure 10**: Probability density functions of  $\delta \text{Nu}(\theta)$  computed using WLe expansions with No = 3, 5, 7 and 9. The right plot shows details of the left tail of the pdf's.
- **Figure 11**: Kinetic energy (left) and  $\delta \text{Nu}(\Theta_h)$  (right) versus hot-wall temperature using WHa expansions with Nr = 2, 3, 4 and 5.
- **Figure 12**: Left: detailed view of  $\delta$ Nu versus  $\Theta_h$  in the neighborhood of the critical value. Right: detailed view of  $\delta$ Nu versus  $\xi$  near the critical value. Plotted are curves obtained using WHa expansions with Nr = 2, 3, 4 and 5.
- **Figure 13**: Mean velocity field  $(P^0\mathbf{u}, \text{left})$  and first wavelet modes,  $\mathbf{u}_{j,k}$  using a WHa expansion with Nr = 5. The scale indices, j, are indicated. At each scale index, frames for different space indices  $k = 0, \ldots, 2^{j-1} 1$  are plotted, and are arranged from bottom to top. The magnitude of the vector is normalized using a factor equal to  $2^{j+1}$ . Due to symmetry with respect to the mid vertical plane, only the left half of the cavity is plotted.
- **Figure 14**: Wavelet modes for the velocity field at a scale index j = 5. The magnitude of the vector is normalized using a factor equal to  $2^{j+1}$ . Results are obtained using a WHa expansion with Nr = 5. The space index k is indicated, and only the left half of the cavity is plotted.
- **Figure 15**: Mean temperature field  $(P^0\Theta, \text{left})$  and first wavelet modes,  $\Theta_{j,k}$  using a WHa expansion with Nr = 5. The scale indices, j, are indicated. At each scale index, frames for different space indices  $k = 0, \ldots, 2^{j-1} 1$  are plotted, and are arranged from bottom to top. Due to symmetry with respect to the mid vertical plane, only the left half of the cavity is plotted.
- **Figure 16**: Wavelet modes for the temperature field at a scale index j = 5. Results are obtained using a WHa expansion with Nr = 5. The space index k is indicated, and only the left half of the cavity is plotted.
- **Figure 17**: Convergence of the expected (left) and standard deviation (right) of Nu with increasing No for the WLe expansion and Nr for the WHa expansion. The errors is estimated using the absolute value of the difference between the solution and the WLe prediction with No = 5.
- **Figure 18**:  $\delta$ Nu versus  $\Theta_h$  (left) and versus  $\xi$  (right) using WHa expansions with Nr = 1, 2, 3, 4 and 5.
